Abstract

We describe the construction and perfomance of a detector system for measuring the all-photon decays of photoproduced mesons in a tagged photon beam with energies

between 4.3 and 5.4 GeV and a flux of 5×10^7 tagged photons per second. The detector was optimized for the detection of the rare radiative decays of the ϕ meson. The primary detector element was a lead glass calorimeter. A single photon energy resolution of 11% at 1 GeV was achieved. Various veto and trigger components are also described. Final states with as many as seven photons were successfully detected and reconstructed.

1 Introduction

The all-neutral detector built for the RADPHI experiment [1] at the U.S. Department of Energy's Thomas Jefferson National Accelerator Facility was designed to detect and measure all-photon decays of ϕ mesons photoproduced in a 50 MHz tagged photon beam. The major component of this detector was a 620-element lead glass electromagnetic calorimeter. This paper describes the design, construction, calibration and operation of this detector. The performance of a detector with the capability of reconstructing all-neutral decays in a photon beam environment is of particular interest to future experiments with photon beams.

1.1 Photoproduced Mesons with All-Neutral Decays

The Continuous Electron Beam Accelerator Facility, CEBAF, at Jefferson Lab provides an opportunity to produce high quality photon beams via incoherent or coherent bremsstrahlung. These photon beams are characterized by high fluxes, high duty factor and superior emittance and make possible, for the first time, high statistics studies of peripherally produced mesons. Indeed, a large part of the planned physics program at an energy-upgraded CEBAF [2] involves the study of exotic hybrid mesons with quantum numbers not allowed within the conventional $q\bar{q}$ model of mesons. Incident photons are expected to be particularly effective in producing these states. In addition, relatively large cross sections for diffractive production of vector mesons, such as the ϕ meson, opens up the opportunity to study their rare radiative decays.

Decays of mesons into two-body combinations of π^o's and η's are particularly interesting and result in all-photon final states. The π^0 nearly always decays into 2γ and a large fraction (43%) of the η decay is into 2γ. A photon detector is sensitive to combinations such as $\pi^0\pi^0$, $\eta\eta$ and $\eta\pi^0$. The first two are constrained to have even spin and the third can have even or odd spin, with

2

Decay	Photon multiplicity
$\phi \rightarrow \text{f}_0(980)\gamma \rightarrow \pi^0\pi^0\gamma$	5γ
$\phi \rightarrow \text{a}_0(980)\gamma \rightarrow \eta\pi^0\gamma$	5γ
$\phi \rightarrow \eta\gamma$	3γ
$\text{b}_1(1235) \rightarrow \omega\pi^)0$	5γ
$\text{a}_0(980) \rightarrow \omega\gamma$	4γ
$\omega \rightarrow \pi^0\gamma$	3γ
$\omega \rightarrow \eta\gamma$	3γ

Table 1

spin one having manifestly exotic $J^{PC} = 1^{-+}$ quantum numbers. Interesting rare radiative ϕ decays involve final states such as $\pi^0\pi^0\gamma$ and $\eta\pi^0\gamma$ – these all-neutral modes being free of backgrounds from internal bremsstrahlung present when charged particles are included in decays.

1.2 Radiative ϕ Decays

The primary goal of the RADPHI experiment was to measure radiative decays of the ϕ meson, $\phi \rightarrow M\gamma$ where M is a pseudoscalar meson (P) such as the π^0 or η or a scalar meson (S) such as the $f_0(980)$ or $a_0(980)$. The decays involving the scalars are rare with branching ratios of order 10^{-4}. The ratio of their branching ratios provides information about the substructure of the $f_0(980)$ or $a_0(980)$ that could determine whether these states are conventional $q\bar{q}$ states, di-quark–anti-diquark states or $K\bar{K}$ molecules [3]. The primary decay modes of the f_0 and a_0 are $\pi\pi$ and $\pi\eta$ respectively. Some meson decays of interest to the RADPHI experiment are listed in Table 1.

Experimental results for the radiative decays of the ϕ to two pseudoscalars have been recently published by groups working at storage rings. These experiments produced the ϕ mesons at rest in e^+e^- annihilations at an energy of m_ϕ equal to 1020 MeV/c^2. These experiments, at DAΦNE [4,5] in Frascati and the VEPP [6–8] in Novosibirsk, provide a clean source of ϕ mesons but the maximum energy of the radiative photon, $E_\gamma^{max} = m_\phi - m_S$, is small, since the scalar mesons of interest have central masses of 980 MeV/c^2, making detection and measurement a challenge. In contrast, if the ϕ is photoproduced in a fixed target experiment, the radiative photon's energy is boosted by as much as a factor of 12 assuming a 6 GeV photon beam. Other differences in ϕ production using photons rather than e^+e^- annihilations make for an important complementarity between the two techniques.

It is seen that all the decays in Table 1 lead to a final state consisting solely of photons. At the energies sufficient to produce these mesons, all of the final-state photons are produced at forward angles in the laboratory frame. Thus a detector for these decays must have sufficient spatial resolution to distinguish several closely-spaced electromagnetic showers in the region close to the forward direction. In the RADPHI experiment, this was accomplished using the Lead Glass Detector (LGD), an array of 620 lead-glass counters, described in Section 3.

In order to limit the rate of triggers to the data acquisition system, it was important to have additional information indicating that a ϕ or other vector meson was produced in the target. In most cases, the photoproduction of a vector meson from a proton target occurs at very forward angles, with a low-energy (typically less than 0.5 GeV kinetic energy) recoil proton emerging at a large angle (typically 40-60 degrees) to the beam direction. In order to detect these protons, a cylindrical scintillation counter system (the BSD) was placed around the production target.

These detectors, as well as various veto counters which served to reduce contamination from unwanted events, are described in Section 3.

2   Accelerator and Photon Beam Line

The CEBAF accelerator at Jefferson Lab is a five-pass recirculating linear accelerator, with superconducting radio-frequency cavities in its two straight sections. The accelerator delivered an electron beam of energy 5.65 GeV to experimental Hall B for this experiment.

A photon beam was generated by bremsstrahlung of electrons striking a thin gold foil. In the early portion of the run a foil $\approx 2 \times 10^{-4}$ radiation lengths was used. Later, due to concerns regarding electron beam-dump heating, the thickness was doubled to maintain the same photon flux at a lower electron beam current. The energy of individual photons was measured by energy analyzing the post-bremsstrahlung electrons using the Hall B tagged photon system [9]. For the RADPHI run only the portion of the tagging system (counters 1 through 19) that tagged photons between 4.38 and 5.38 GeV was used, that is between 77 and 95% of the electron beam energy. The electron current was selected such that the total tagged photon rate was 5×10^7 per second.

The photon beam remained in vacuum for about 10 meters beyond the tagger.

Fig. 1. A cutaway overview of the RADPHI detector. The CPV, located immediately upstream of the LGD, has been omitted for clarity.

It then emerged through a thin window into a 30-meter long polyethylene bag filled with helium. The bag terminated a few centimeters upstream of the RADPHI target. Monte Carlo studies and early beam tests indicated that this helium bag was a satisfactory solution to the problem of background generated by the beam passing through air. The distance from radiator to target was 40 meters. The photon beam dump was downstream of the RADPHI apparatus.

3 Experiment Hardware

3.1 Detector Overview

The RADPHI detector is shown schematically in Fig. 1 and its major components are listed in Table 2.

The beam was incident on a 2.66-cm diameter, 2.54-cm long beryllium target. These dimensions were chosen on the basis of GEANT Monte Carlo studies which took into consideration beam size, recoil energy loss, and detector rates. The target was suspended centered on the beam axis with three 28 AWG steel wires from a 50 cm diameter Plexiglas ring. A computer-controlled stepper motor could rotate the target into and out of the beam. Its single-step capability enabled beam-target scans to be performed remotely.

Surrounding the target and extending forward to 30° from the beam axis was a cylindrical scintillator detector (BSD) which provided nearly full angular coverage for recoil protons. Surrounding the BSD was a cylindrical lead-scintillating fiber photon detector (BGD) which served to reject events (off-

line) with large angle photons.

The primary detector component was a 620-channel lead-glass wall (LGD) assembled to approximate a circle around the beam line with a $8 \times 8 \text{cm}^2$ central hole for the passage of the beam.

A 30-channel scintillator array (CPV), to veto (off-line) charged particles in the final state, was located upstream of the lead-glass array.

Upstream of the target and all detectors was a 10-cm thick shield wall made of lead poured into a steel jacket. A hole through the wall permitted the photon beam to pass to the target. Mounted upstream of the wall was a lead and steel collimator (not shown) with inner diameter 6.5 cm, larger than the beam but smaller than the beam hole through the LGD. A scintillator hodoscope (UPV) was placed just downstream of this wall in order to veto beam halo interactions on the inner surface of the collimator. The hodoscope consisted of six horizontal and two vertical paddles, arranged around a square opening the size of the helium bag.

In the following sections each detector element is described in more detail. In these descriptions, a right-handed coordinate system is used with the origin at the center of the target with the z-axis along the beam direction and the y-axis is up.

The active elements of the array were lead-glass bars recycled from the Brookhaven National Lab (BNL) E852 detector [10]. The dimensions of the bars were 4 cm × 4cm × 45cm. The long axis was oriented along the beam. The bars were wrapped in 0.0005 inch thick aluminized mylar and stacked in a 28 × 28 matrix. The four central blocks were removed to permit the unscattered photon beam to pass to the beam dump. The phototubes were held in place relative to the lead-glass array, one tube per block, with an air gap for coupling. The entire assembly was enclosed in a light-tight box of Herculite.

The lead-glass detector was positioned 1.07 m downstream of the target and subtended an angle of approximately 27° from the beam line. Many of its technologies were identical to those used in experiment E852[11] at BNL in 1994 and 1995. The array was housed inside a steel frame on a transporter (see Fig. 2), which rolled on rails under the control of a drive system. The blocks rested on a steel platform which could be raised or lowered via an independent drive system. The dual systems permitted alignment of the array, while the horizontal system facilitated removing the lead-glass from the beam line between RADPHI running periods.

The phototubes were Russian-built FEU84-3 photomultiplier tubes with Cockcroft-Walton bases[12] designed and manufactured for RADPHI to reduce cabling and heating. Each base was powered externally by a low-voltage (15V) DC power supply, distributed via ribbon cable. Internally, an oscillator and a capacitor-diode chain multiplied the voltage to 175V DC, which drove a second chain that provided the voltages to the stages of the phototubes. The second stage was driven from both ends to eliminate voltage sag at both the photocathode of the tube and the anode.

The voltage for each base was individually controllable on a serial signal bus. Bases were assigned unique 16 bit addresses to identify row and column positions in the detector. This addressing permitted individualized voltage settings. A base could also be instructed to output a pulse with a total charge proportional to its voltage, for diagnostic purposes.

Monitoring of the lead-glass array was accomplished via a pulsed laser. A Laser Photonics LN-300C nitrogen laser illuminated a small block of scintillator which in turn illuminated a group of optical fibers. The fibers transported the light to a 1.27-cm thick sheet of polished Plexiglas. The upstream face of the sheet was covered in aluminum foil. The fibers terminated at the edges of the sheet inside which the light was distributed, a sufficient amount of it escaping into the lead-glass stack. Except around the three-inch hole in the center, where the intensity peaked, the illumination was quite uniform. Firing

of the laser and subsequent phototube readout were coordinated as a special trigger initiated periodically during the run. The laser monitoring system was useful for setup and debugging, for initial gain adjustment and relative gain monitoring of the LGD.

3.3   The Barrel Calorimeter (BGD and BSD)

Two concentric barrel-shaped detectors, both built for the Jetset experiment [13,14], surrounded the target. These detected particles emerging from the target between 30° and 90° from the beam axis. The inner detector was a hodoscope made up of three layers of overlapping paddles. The innermost layer consisted of 12 paddles twisted to spiral around the barrel in a clockwise direction (looking downstream). The middle layer of the barrel scintillator array consisted of 12 paddles twisted to spiral counterclockwise. The outermost layer of the array was 24 paddles all parallel to the beam axis. A three-layer coincidence defined a triangular region, called a pixel, used to reconstruct recoil particle directions in the off-line analysis. All 48 paddles were instrumented with Thorn-EMI 9954 phototubes.

Surrounding the scintillator array was a lead/scintillating fiber calorimeter. RADPHI installed it to detect photons that emerge at large angles beyond the solid angle of the forward calorimeter. Upstream light readout was accomplished with 45°-bend light guides, the light being measured with Philips XP2020 phototubes. Constrained to fit into a small space just upstream of the forward detectors, the downstream light collection system consisted of a pad of Bicron (BCF-92), 1.5-mm square, multi-clad wave-shifting fibers positioned at the end of the scintillating fibers. Light from the fibers was detected by Thorn-EMI 9954 phototubes.

3.4   The Charged Particle Veto (CPV)

The Charged Particle Veto (CPV) scintillator hodoscope was installed upstream of the lead-glass wall to tag charged particles. The hodoscope shadowed the upstream face of the lead-glass stack and so provided the capability of vetoing (off-line) events that contained charged particles in the final state. It was made up of 30 horizontal paddles, fifteen each side of center. The paddles were arranged so that neighbors overlapped both vertically and at the center (except, of course, around the beam hole).

The paddles closest to the beam were narrower to equalize (approximately) rates in the detector. Rates were so high, however, that zener diode bases were installed on the outer sixteen paddles and transistorized bases were installed
Fig. 2. The LGD transporter. The glass stack is shown, with the 620 instrumented elements for clarity.

on the inner fourteen. In addition, phototube voltages were run at the low end of the efficiency plateau and signals were amplified by a $5\times$ amplifier before being split and analyzed. The phototubes were Thorn-EMI 9214B's.

3.5   Electronics

Photon tagger signals were discriminated with Phillips 715 constant fraction discriminator modules and the digital signals were brought to TDCs at the opposite end of the hall along 190 ± 2 feet-long RG-58 cables. A logical OR of signals from the tagger hodoscope was sent through a 0.75c propagation-speed coaxial cable, type LM-240, to the trigger electronics.

Signals from all RADPHI detectors except the lead-glass array were split by impedance-matching splitters. One set of splitter outputs was sent through RG-174 cable to discriminators. The discriminator for the upstream hodoscope was the LeCroy 3412; for the barrel scintillator array, the LeCroy 3412A; for the barrel lead/scintillating fiber calorimeter, the LeCroy 3420 (constant-fraction); and for the charged-particle hodoscope, the LeCroy 4413. Discriminator outputs went to LeCroy 1877S FASTBUS TDCs in common stop mode, Struck 7200 VME scalers, and, in some cases, the trigger logic.

The other set of outputs was sent through RG-58 cable to custom, 12-bit, integrating ADCs developed by Indiana University for E852.[11] While gated,
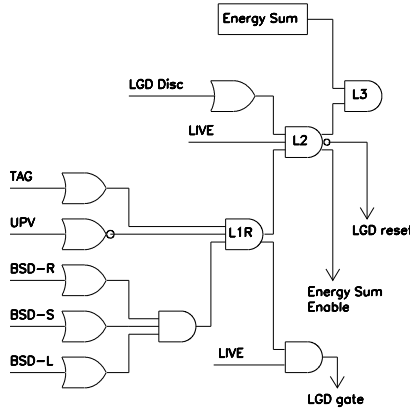

Fig. 3. The RADPHI trigger logic. L1R denotes Level-1 raw, Level 1 included L1R in coincidence with LIVE.

each ADC channel sampled a 16-ns baseline and integrated the signal for the remaining ∼100 ns of the gate. The integrated charge was discriminated against two independent thresholds for use in higher level triggers, and digitized with a 12-bit successive approximation digitizer. The integration and discrimination circuitry for each channel was housed on a daughter card for easy replacement in case of failure. Digitization began 750 ns after the end of a gate and took 4 μs.

The two discriminators on each channel were arbitrarily designated the "high" and "low" discriminators. The thresholds of all ADC discriminators were set during initialization of a data-taking period. The state of the two discriminators were represented as bits in the data word and also presented on the auxiliary FASTBUS backplane ∼100 ns after the end of the gate. The low discriminators were used in the second level trigger, and the high discriminators were used in the third level trigger.

The ADCs were read out in FASTBUS block-transfer mode. To reduce event size, only ADC channels with values at least 5 counts above pedestal were recorded. The typical pedestal width was 0.6 count.

3.6 Trigger

RADPHI employed a multi-level trigger (see Fig. 3), described below.

10

3.6.1 Level 1 trigger

The first level was a logical coincidence of the signals from the barrel scintillator array and photon tagger in anti-coincidence with the upstream veto array, during the LIVE condition from the hardware trigger supervisor. When the first level trigger condition was satisfied, the electronics generated gates for the ADCs and common-stop signals for the TDCs, initiated the second trigger level processing, and blocked further triggers until additional logic decided to reject or read out the event.

3.6.2 Level 2 trigger

The second level trigger requirement was a logical OR of the levels from the lead-glass detector ADC discriminators. This requirement selected events with at least one element of the lead-glass detector containing a minimum amount of energy, typically about 1 GeV. In the case the level 2 trigger was not satisfied, the ADCs and TDCs were reset, requiring 250 ns, before another trigger could be received. The total incurred dead time was about 1.2 μs. The majority of the dead time of the experiment was from events that failed at level 2, so this reset time was a critical parameter.

3.6.3 Level 3 trigger

The third level trigger was a digital sum of the total energy in the lead-glass calorimeter. The sum was computed by a processor module designed and built by Indiana University for BNL E852. An 8-bit representation of the energy was presented to a LeCroy 2372 memory lookup where the value was compared to a threshold value equivalent to roughly 3 GeV.

In the event the level 3 trigger was not satisfied, a clear was sent to the TDCs. The ADC had already digitized, so no resetting was necessary. The minimum dead time for an event that failed at level 3 was 8.5 μs. For every channel read into the energy sum module, this number increased by about 450 ns. The typical dead time incurred for a level 3 FAIL was 10 to 12 μs. In case of a level 3 PASS, the event was recorded.

4 Calibration

4.1 LGD calibration

The LGD calibration procedure was based upon the fact that when the positions and energies of individual showers in the calorimeter are combined to form an invariant mass, the mass spectrum exhibits prominent peaks corresponding to known mesons decaying into $n\gamma$ final states, eg. π^0, η, η', ω. These peaks are already visible in the reconstructed spectra before the gain calibration has been carried out, even when individual tubes vary in gain by a factor of 2 or more. The gains were set during the experimental run by adjusting the high voltage on individual tubes until their responses to an injected light pulse from the calibration laser were approximately equalized. The pulser equalization procedure was repeated periodically throughout the run to take into account changes in the response of individual blocks arising from radiation damage and other sources of long-term drift during the experiment. Inhomogeneities in the light distribution led to physical gains on particular channels that differed by more than a factor of two from the mean, with a 25% r.m.s. deviation. The goal of the offline calibration was to measure these gain factors using experimental data, so that they could be used in turn to correct the data during reconstruction.

A calibration procedure based solely upon the reconstructed masses of known mesons appears to be problematic because it seeks to exploit one constraint (the known mass of the meson) to estimate multiple parameters (gain correction factors for every channel that contributes energy to the event). When many events containing a contribution from a given block are superimposed, however, the dependence of the average reconstructed mass on the gains of neighbor blocks tends to wash out, leaving the bias that comes from the gain of the block itself. Removing this bias by applying a gain correction to this channel leads to a narrower peak in the mass plot. This is accomplished quantitatively by adjusting individual gain factors to optimize a single global function of the data, given in Eq. 1,

$$F = \sum_{i=1}^{N}(m_i^2 - m_0^2)^2 + 2\lambda \sum_{i=1}^{N}(m_i^2 - m_0^2), \tag{1}$$

where N is the number of events in the calibration data sample and i denotes a single event in that sample. The masses m_0 and m_i are the physical mass of the meson being used for the calibration and the reconstructed mass in the LGD for event i. The first term in F measures the width of the reconstructed mass peak, while the second term is introduced with the Lagrange multiplier λ to embody the constraint $< m_i^2 > = m_0^2$.

For the purposes of RADPHI , the most convenient meson for calibration turned out to be the π^0 which appears as the dominant structure in the 2γ invariant mass plot for 2-cluster events. All events that were reconstructed with exactly two clusters and whose invariant mass lay within $\pm 30\%$ of the center of the π^0 peak were candidates for the calibration sample. The 2γ invariant mass is given by

$$m_i^2 = 2p_{1i}\,p_{2i}\,(1 - \cos\gamma_i), \tag{2}$$

where p_{1i}, p_{2i} are the reconstructed energies of the two showers, γ_i is the angle between the centers of the two showers as viewed from the target and $c = 1$.

The reconstructed energy p_{ji} is approximately equal to the observed energy s_{ji} in shower j, but contains additional nonlinear corrections to account for angle-dependent attenuation and output coupling effects,

$$p_{ji} = (1 + g) \sum_{k \in S_j} E_{ki} = (1 + g)s_{ji}, \tag{3}$$

where k labels an individual block contributing to shower j. The nonlinearity correction factor g is weakly dependent on the observed shower energy s_{ji} but not on the block energies E_{ki} individually. A calibration step consists of introducing a small channel-dependent gain correction factor ϵ_k such that $E_{ki} \to E'_{ki} = (1 + \epsilon_k)E_{ki}$, where the prime is used to denote the corresponding quantity after the gain correction is applied.

Minimizing F in Eq. 1 directly with respect to the variables ϵ_k is made difficult by the nonlinear dependence of m_i on the block energies that appears in the factor g in Eq. 3 and also in γ_i. Progress can be made by observing that small shifts in the gain of a single channel will have little effect on the nonlinear correction factors or the shower centroids, but will rescale the p_{ji} of its shower:

$$\frac{\partial p'_{ji}}{\partial \epsilon_k} \simeq p_{ji}\frac{E_{ki}}{s_j}. \tag{4}$$

$$\frac{\partial m'^2_i}{\partial \epsilon_k} \simeq m_i^2 \frac{E_{ki}}{s_j}. \tag{5}$$

These approximations lead to a linear equation which is satisfied at the minimum of the penalty function F.

$$\frac{\partial F'}{\partial \epsilon_k} = 2\sum_{i=1}^{N}(m'^2_i - m_0^2)\frac{\partial m'^2_i}{\partial \epsilon_k} + 2\lambda \sum_{i=1}^{N}\frac{\partial m'^2_i}{\partial \epsilon_k} \tag{6}$$

13

$$= 2 \sum_{i=1}^{N} \left(m_i^2 - m_0^2 + \lambda + \sum_{k'} \epsilon_{k'} \frac{\partial m_i'^2}{\partial \epsilon_{k'}} \right) \frac{\partial m_i'^2}{\partial \epsilon_k}$$
$$= 0$$

The solution is given by

$$\epsilon_k = [C^{-1}]_{kk'} (D - \lambda L)_{k'}, \tag{7}$$

where

$$C_{kk'} = \sum_{i=1}^{N} \left(\frac{\partial m_i'^2}{\partial \epsilon_k} \frac{\partial m_i'^2}{\partial \epsilon_{k'}} \right)$$

$$D_k = - \sum_{i=1}^{N} \left((m_i^2 - m_0^2) \frac{\partial m_i'^2}{\partial \epsilon_k} \right)$$

$$L_k = \sum_{i=1}^{N} \frac{\partial m_i'^2}{\partial \epsilon_k}$$

and the value of λ is fixed by the condition that the centroid of the reconstructed mass peak must lie at the physical mass:

$$\lambda = \frac{B + L^T C^{-1} D}{L^T C^{-1} L}, \tag{8}$$

where B is the mass bias $\sum_{i=1}^{N} (m_i^2 - m_0)^2$. Starting off with a nominal gain factor of unity for all channels, gain corrections are calculated using Eq. 7 and applied iteratively until the procedure converges to $\epsilon_k \to 0$ for all k. In practice, it was found that special care must be taken in the way that the matrix C is inverted. C is a square symmetric matrix with 620 rows and columns whose elements are determined statistically by sampling a finite sample of N calibration events. Even for very large samples there are instabilities that appear when taking the inverse C^{-1} which demand careful treatment. The nature of these instabilities can be best understood by expressing C^{-1} in terms of its spectral decomposition,

$$[C^{-1}]_{kk'} = \sum_{\alpha} \frac{1}{c(\alpha)} e_k(\alpha) e_{k'}(\alpha), \tag{9}$$

where $c(\alpha)$ are the eigenvalues and $e(\alpha)$ the corresponding orthonormalized eigenvectors of C. Of the 620 eigenvalues of C, there are generally a few whose values are very small and statistically consistent with zero. These terms tend to dominate the behavior of C^{-1} if it is calculated using exact methods. A better approach instead is to truncate Eq. 9 and include only eigenvectors

in the sum whose eigenvalues are adequately determined by the data. This truncation implicitly recognizes that there are some linear combinations of the gains which cannot be determined from the given data sample, and simply leaves them unchanged from the initial conditions. This method does not fix a subset of the ϵ_k values to zero on a given step. Good convergence was obtained after 8-10 iterations.

5 Event reconstruction

5.1 Cluster pattern recognition

A photon incident on the LGD deposits energy in several LGD blocks. When these blocks are associated with each other, the position and energy of the incident photon can be measured. The algorithm to associate groups of blocks into "clusters" has three steps.

As a first step the algorithm finds the highest energy block in the LGD, called the "seed" block. Neighboring blocks are associated with the seed block into a cluster. Once one cluster is completed, the blocks in the cluster are removed from the list of active blocks and the process is repeated until the highest energy block remaining is below some value, typically 150 MeV. At this stage the found clusters are no larger than three by three blocks and not all blocks in the original list are used, i.e. associated with a cluster.

In the second step, the clusters are expanded by incorporating unused blocks contiguous with clusters into the original groups. If a block is near two step-1 clusters, the block is associated with both clusters, its energy shared in proportion to the energy contained in the central portion of the clusters.

The third step repeated step 1 but allows a seed block to have a lower minimum energy, typically 50 MeV.

Once all possible seed blocks are exhausted, the photon positions and energies are determined.

5.2 Shower position and energy corrections

To a first approximation, the total energy of a reconstructed shower is equal to the sum of the observed energy in each of the blocks that belong to a cluster, associated using the algorithm described in Sect. 5.1. Improved resolution can usually be obtained by introducing a small nonlinear correction that takes into

account a few-percent increase in the response of lead glass to showers above 1 GeV because of attenuation and light-collection efficiency effects in the blocks [15]. However the problem of shower reconstruction in the RADPHI experiment demands a more sophisticated approach than a simple nonlinearity correction because of the fact that so many of the reconstructed showers are far from normal incidence.

To find the direction of the photon, a vector is constructed beginning at the center of the target and ending at the point (X_c, Y_c, Z_m) where X_c and Y_c are the measured coordinates (discussed below) of the shower centroid in the transverse plane of the LGD and Z_m is the longitudinal coordinate of the maximum of the shower profile inside the LGD. Determination of the the the dependence of the reconstructed momentum upon the unmeasured coordinate Z_m is especially important for showers far from normal incidence. The acceptance of RADPHI depends upon reconstructing showers as far as $25°$ from the normal, where the angle of incidence cannot be ignored. Furthermore at angles beyond $20°$ there are increasing effects from shower leakage out of the sides of the array, which introduces a bias in both the shower coordinates and the energy. The RADPHI analysis relies on a detailed Monte Carlo shower simulation to map in three dimensions from unknowns (θ, ϕ, E), to measured values (X_c, Y_c, S) where E is the true energy of the photon while S is the observed energy summed over the cluster. Incident photons are generated in the target over a fine grid in both direction and energy, and the standard cluster algorithm is used to find the average centroid and observed energy for each grid point. This map is parameterized using an expansion in a suitable set of basis functions to obtain algebraic forms for $X_c(\theta, \phi, E)$, $Y_c(\theta, \phi, E)$ and $S(\theta, \phi, E)$. This system of equations is then inverted using an iterative solution during analysis to provide corrected estimates for (θ, ϕ, E) for each reconstructed shower.

As an example, a slice through the function $S(\theta, \phi, E)$ is shown in Fig. 4 for $\phi = 0$ and a range of values for E. The data points in the figure represent the average reconstructed shower energy for the given generated sample. The error bars show the r.m.s. spread in the reconstructed values that come from photoelectron statistics and shower fluctuations. The curve is the algebraic parameterization that emerged from a fit to a general form for $S(\theta, \phi, E)$. The depression in the response at normal incidence is an interesting effect that was discovered using this simulation, as discussed next.

The Monte Carlo shower simulation relies on the standard RADPHI Monte Carlo framework based upon GEANT3 [16]. Inside the LGD blocks the response of the lead glass is simulated in detail by the explicit creation and following of individual Cerenkov photons as they are produced in the development of the shower. The Cerenkov spectrum in the simulation is limited at low frequencies by the response of the photocathode (cuts off below 1.8 eV)
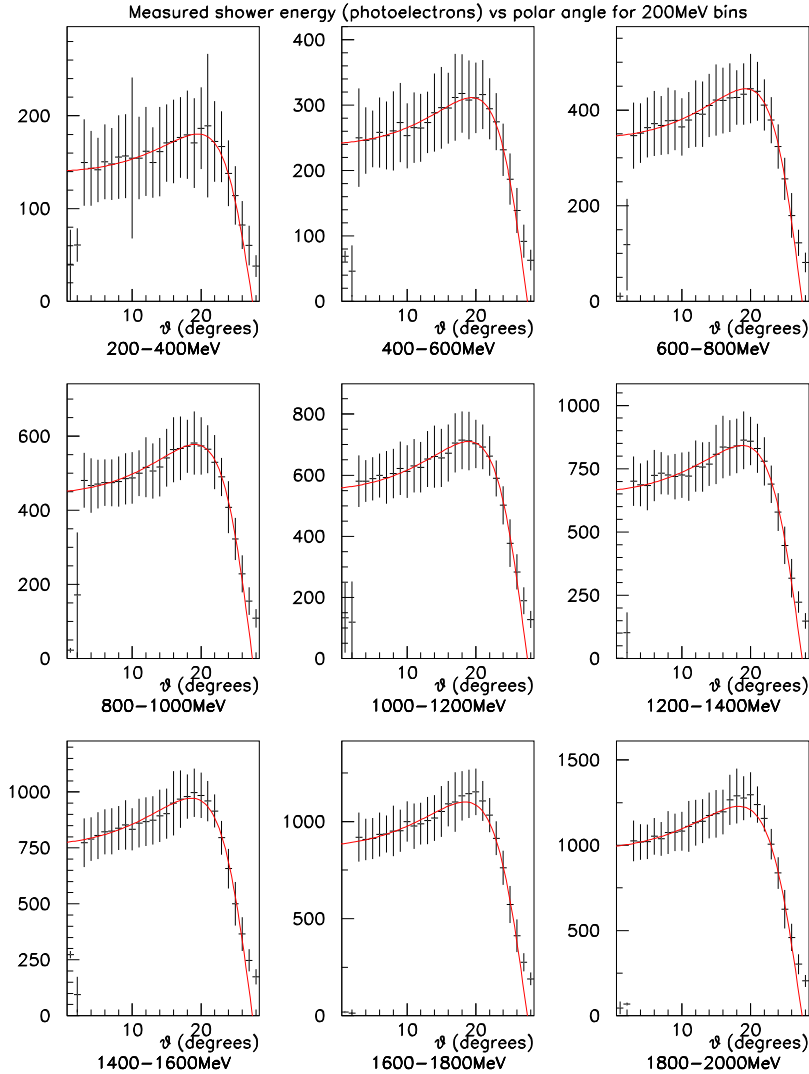

Fig. 4. Measured photoelectron yield in LGD as a function of angle for gammas generated in the target at $\phi = 0$. The generated shower energies are distributed uniformly within the respective energy intervals. The data points are the average and r.m.s. yields for a sample of several hundred simulated showers. The curve is a fit to the data.

and at high frequencies by the attenuation curve of lead glass (cuts off above 4.1 eV). Between these two limits the photocathode efficiency, the attenuation of lead glass and the refractive index are all included with their known frequency dependence. Cerenkov light is polarized and polarization effects are treated exactly when reflection and transmission are simulated at the boundaries of the lead glass. The typical Cerenkov photon undergoes a number of reflections before reaching the photocathode or being absorbed. Wrapping the blocks with a thin layer of air between the glass surface and the surrounding aluminized mylar layer was an important factor in the simulation, as was the

presence of an air gap at the interface between the block and the phototube. One consequence of the latter which was only realized after the simulation was carried out is that light emitted at the critical Cerenkov angle of 52° by a particle moving parallel to the block axis has zero probability of being detected at the phototube; these photons are entirely contained inside the block by total internal reflection.

Two important consequences follow from this observation. The first is that the overall shower response goes through a local minimum at normal incidence, where a large fraction of the shower particles are in the "blind spot" with momenta nearly parallel to the block axis. The simulation showed that at 20° the light output from a 1 GeV shower was about 20% greater than at normal incidence. The second consequence is that the observed lateral size of a shower must be larger than the size expected based upon the unweighted shower profile. This follows from the fact that the most energetic particles in a shower are found near the center of the shower profile, and these are the particles whose directions are most likely parallel to the block axis. The observed light yield coming from the core of the shower distribution is thus suppressed relative to light coming from the shower periphery where particle energies are low and directions are nearly random. In fact, there was a discrepancy of nearly 50% between observed shower size in RADPHI data and Monte Carlo before this angle-dependent collection efficiency was discovered. After the effect was included in the simulation, the shapes of real and simulated showers were examined in terms of spatial moments up to the fourth moment, and they were found to be in agreement within errors.

6 Performance

6.1 Timing and rates

The RADPHI experiment ran for a total of about 1000 hr with photon beam on target. Data taking was divided into runs of 1-2 hr duration. Data were saved on local disk and then migrated offline to permanent storage on the Jefferson Lab Mass Storage System. An average of 350 events were collected by the data acquisition system per second. The average event record size was 600 bytes, leading to a modest data rate of 200 kB/s. For approximately the first half of the run period, a radiator of nominal $2 \cdot 10^{-4}$ radiations lengths thickness was used with an electron beam current of 130 nA. For the second half the radiator thickness was increased to $3 \cdot 10^{-4}$ radiation lengths and the electron beam was turned down to 77 nA. At a distance of 40 m from the radiator, the RADPHI target of radius 12.8 mm intersected over 95% of the photon beam. When the RADPHI target was moved out of the beam, rates in the detector

Table 3
Signal rates, widths and dead-time factors for the major components of the RADPHI detector. Rates shown are those obtained at full operating intensity.

signal	rate (Hz)	duration	dead-time fraction
taggerOR	$5.0 \cdot 10^7$	5 ns	0.07 [1]
cpvOR	$8.2 \cdot 10^7$		0.04 [2] [4]

scintillator elements dropped by about one order of magnitude.

All of the signals that are relevant to the event trigger are listed in Table 3. The gate for the ADC's and TDC's was generated from the level-1 trigger (see Fig. 3). The high rate in the *cpvOR* prevented its use as a veto in the online trigger. The total proton photoproduction cross section integrated over the bremsstrahlung spectrum of the beam from pion threshold to the end-point leads to a total hadronic rate in the RADPHI target of 150 kHz. Increasing this rate by a factor of two to account for neutron photoreactions still does not

approach the order of magnitude of the observed rates in the BSD and CPV.

GEANT-based Monte Carlo simulations of the RADPHI experiment, including the beam line, predict rates in agreement with those shown in Table 3 coming from electromagnetic backgrounds alone. Most of the rate of charged particles coming from showers originating in the target is confined to angles a few degrees from the beam but the tails of this distribution extend out as far as 60°, accompanied by a diffuse omni-directional background of low-energy deltas and gammas. The energy distribution of this background peaks in the few MeV region, except in the area immediately surrounding the forward beam hole where the typical energies are tens of MeV. The hard component coming from pair conversions of energetic beam gammas in the target escape through the forward beam hole and do not affect the experiment. Evidence that soft backgrounds of this sort are the dominant contribution to the rates in the trigger counters is seen in the marked decrease in Table 3 going from the innermost BSD layer *bsdOR-2* to the middle and outer layers. These three layers are in immediate contact with each other, with only the material of 5 mm of plastic plus two layers of tape shielding an outer layer from the flux seen by its inner neighbor. The fact that such a small amount of material led to a decrease in the observed rate by nearly a factor of two indicates that the source of the rate is primarily a few MeV-scale background.

The hit rate in the BGD was a strong function of threshold. During the early stages of the run, the BGD counters were operated at a low threshold corresponding to an electron-equivalent energy of 5 MeV. Under these conditions the total rate in the BGD was 800 kHz at standard operating intensity, as shown in the table. The BGD gains were lowered by a factor of 4 later in the run, effectively raising the thresholds to 20 MeV. This reduced the inclusive BGD rate to 120 kHz, in agreement with expectations based upon a total nuclear interaction rate of 300 kHz and 40% solid angle for the BGD acceptance. This observation is consistent with Monte Carlo simulations which show that the background rates in the barrel are dominated by hadronic sources for energies above 20 MeV. This is considered an effective lower bound on the energy of showers that may be reconstructed in the BGD.

There were no scalers or TDC's on the LGD signals so there is no direct measurement of the rates in the forward calorimeter. Instead these rates have been inferred from the increase with beam current in the observed energy for a given block within the ADC gate. A minimum-bias trigger was formed by disabling levels 2 and 3 and accepting all level-1 events. By deriving the trigger from barrel and tagger elements only, an unbiased view of what is happening in the forward detectors is obtained. This view contains two components, one which is correlated to the trigger in the barrel (hadronic events are likely candidates) and the other which is uncorrelated with the barrel and consists of random forward hits that happen to fall within the 100 ns ADC gate. These

two components are distinguished by running two minimum-biased runs under unchanged beam conditions, one at full beam intensity (77 nA) and the other at low intensity (2 nA).

The rate in a block is defined as the number of events within a given data set with the block's ADC over threshold divided by the gate width. This rate is the sum of the barrel-correlated component which does not depend on beam current (a constant probability divided by a constant gate width) and the barrel-accidental part which is linear in beam current and disappears in the limit of low rate. When the beam current was turned down from 77 nA to 2 nA the rates across the LGD decreased by only a factor of about 8 instead of the factor of 38 expected if only accidentals were present. On the other hand, if only barrel-correlated hits were present in the LGD then this rate should have been independent of beam current. This shows that at 77 nA the LGD inclusive rates are accidentals-dominated and at 2 nA they are dominated by the barrel-correlated component.

Within errors, the inclusive LGD rate that would be measured on a free-running scaler connected to each block is simply the difference in the above-defined block rates between the high and low-intensity runs. These rates are plotted as the data points in Fig. 5a as a function of the distance of the block from the beam axis. The histogram in the figure is the Monte Carlo estimate for the LGD rates arising only from electromagnetic background. Note that for individual blocks, the expected hadronic rate is negligible on this scale. The excess of the data over Monte Carlo at large radius suggests that there are sources of background in the experimental hall that are not included in the simulation. The simulation includes the principal components of the Hall B photon beam line starting at the radiator and including the (empty) CLAS target and downstream yoke aperture. It was on the basis of this simulation that the helium bag and lead shielding wall upstream of the RADPHI experiment were introduced. An excellent agreement between observed and predicted rates is seen across most of the face of the LGD. The ADC threshold used in the Monte Carlo for this comparison is 15 MeV, which corresponds to the online threshold that was applied to the LGD data by the data acquisition.

Note that in Fig. 5 a marked depression appears at small radius, relative to the observed rates. These blocks are in the vicinity of the beam hole and, in addition to suffering from the highest rates, these blocks also suffered from radiation damage. The eight blocks closest to the beam axis (first data point) are the most affected, but some effects can be seen at neighboring points. These data which were taken toward the end of the RADPHI run period provide a quantitative measure of the effects of radiation damage on the response of the LGD. More insight can be provided by the pulse-height spectrum of these background hits in the minimum-bias sample. All of the spectra show a maximum intensity at threshold and an exponential tail that extends to the
Fig. 5. Characteristics of unbiased flux observed in individual blocks in the LGD as a function of distance from the beam. The points are derived from data and the histograms from a Monte Carlo simulation of the electromagnetic background coming from the beam and target. Rates (upper panel) and average energy (lower panel) include all hits over 15 MeV.

GeV region. The mean of this distribution is plotted in Fig. 5b as a function of block distance from the beam axis. As in Fig. 5a the points are the data and the histogram is the Monte Carlo prediction. The comparison is sensitive to the exact threshold used, which was 15 MeV for Monte Carlo but varied between 10 MeV and 20 MeV for real data, depending on the channel. Even with this caveat, the general trends are very similar between data and Monte Carlo, including the forward rise that is expected based upon the kinematics

22

of electromagnetic showers. The depression of the response of the innermost blocks is due in part to radiation damage, but also to the fact that these blocks contained so much background that the calibration procedure tended to artificially suppress their gains relative to their neighbors in the interest of optimizing the total shower energy resolution.

6.2   Photon tagging at high rates

Nominal operating conditions called for an inclusive rate of $5 \cdot 10^7$ /s in the tagging counters, which defined the region of interest in the incident beam spectrum from 77% to 95% of the end-point energy. The electronic sum of the signals from these 19 tagging counters, called the *taggerOR*, was included in the level-1 trigger to ensure that every trigger had a hit in at least one tagging counter within the tagging coincidence window of 20 ns.

By conventional standards for tagged photon experiments, $5 \cdot 10^7$ Hz is a high rate that requires special care in the treatment of accidental coincidences. On average, within the online coincidence window of 20 ns one accidental tagging coincidence is expected in addition to any true coincidence that might be present for a given event. After the timing differences between channels have been eliminated in the offline analysis and the timing resolution optimized by correcting for signal propagation delays, the coincidence window can be reduced to a few ns, at which point the accidentals probability is reduced well below unity. Even then, it is a mistake to suppose that accidentals can be ignored in the analysis. The reason for this is that, with a level-1 trigger dominated by background as in the case of RADPHI the number of accidental tags can outnumber the true tags even if the absolute probability for accidentals on a given event is small compared to unity. As an example, consider an analysis in which the final accidental probability is 30%. If only 10% of the experimental triggers correspond to actual tagged photons interacting in the target then a 30% accidentals probability leads to a ratio of 3 in accidental/true coincidences in the tagged event sample. These are the approximate conditions for the RADPHI analysis.

The correct treatment of these accidentals is to repeat the entire analysis for any observable twice, the first time with all spectra weighted by the number of tagging hits inside the (offline) coincidence window and the second time weighted by the number of tagging hits inside a window of similar width but shifted to exclude the coincidence peak. This shifted window is known as the "accidentals window" and spectra weighted with the tagged accidentals weight are known as "accidental spectra." Spectra weighted by the number of tagging hits inside the coincidence window are called "coincidence spectra." Coincidence and accidental spectra can be formed for an arbitrary observable

in the experiment. Their difference leads to accidentals-subtracted spectra or "tagged spectra" which reflect both in shape and magnitude what would have been measured if only the tagged component of the beam had been present. Apart from the inflation of the statistical errors which follows from the weighting and subtraction, the tagged spectra are identical to what would be obtained if the bremsstrahlung beam outside the tagger momentum window were absent and only the beam photons coming from electrons counted by the tagger were present in the beam.

The way that photon tagging is carried out in the RADPHI analysis is modified by the fact that the rates in the CPV are even higher than the tagger. Rates in the individual CPV counters are only a few MHz but the inclusive rate is over 80 MHz, too high to permit an efficient online veto and high enough to demand special care in the timing optimization and the treatment of accidental vetos in the offline analysis.

The most accurate time reference in the experiment comes from the tagger. The time resolution of this reference is about 500 ps, limited by the TDC. With the tagger time as a reference, the time spectra of the CPV counters exhibit a small coincidence peak of about 2.5 ns f.w.h.m. over a large continuum of accidentals. Even though the peak itself is a small bump on top of a large continuum, it actually represents 80% of all tagged events. Hence it is essential that a charged particle veto be applied before events can be analyzed in terms of all-neutral final states.

In the offline analysis, the charged particle (CP) veto is applied by taking each hit in the CPV counters and eliminating all tagging hits within the range of the CP-coincidence peak described above. The way to minimize accidental vetos is to use as narrow a veto window as possible, without allowing charged final states to leak into the sample. A veto window of 6 ns is sufficient to contain the entire CP peak at a cost of only 30% in accidental vetos. The CP veto is applied in the offline analysis simply by eliminating from the tagger hit list any hits which are associated with CPV hits. This is done before the tagging weights are computed, so that only the beam particles that cannot be associated with forward-charged final states are considered "tagged." Done in this way, the suppression of events with charged tracks in the forward region is carried out as a part of the statistical tagged beam analysis rather than as a cut on an event-by-event basis.

The event sample that remains after charged final states have been eliminated must derive its timing from the barrel scintillators where a hit from a charged track, presumably the recoil proton, was required by the trigger. The overlap of counters in the three layers of the BSD forms a "pixel" which marks the point of impact of the track on the surface of the barrel. Knowledge of the position of the impact allows the light-propagation time to be subtracted from the times
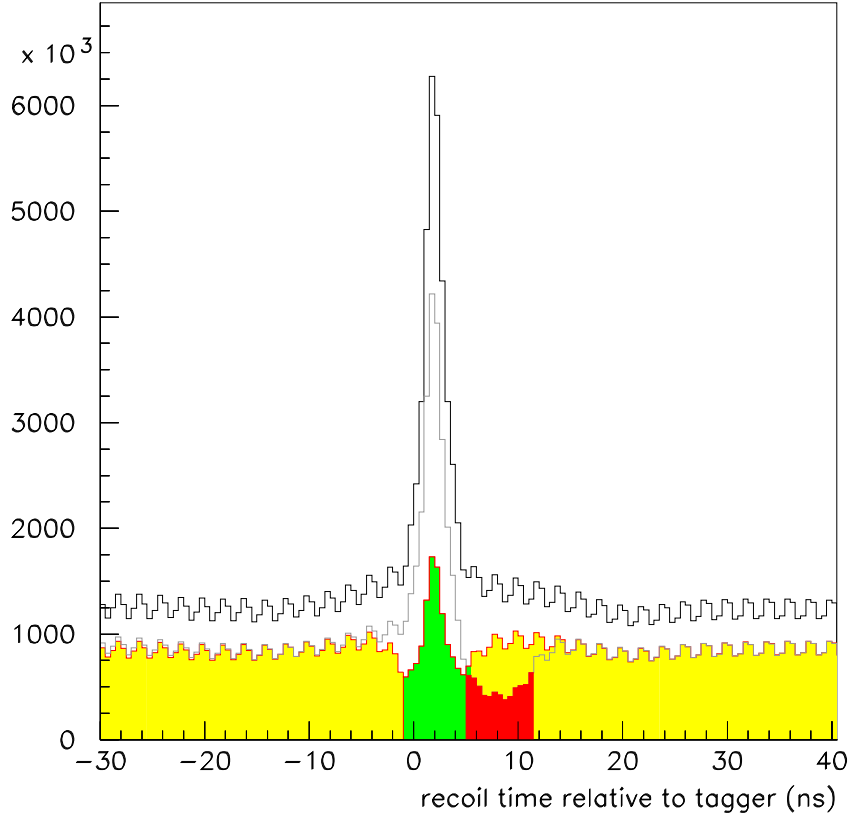

Fig. 6. Spectrum of the recoil time relative to the tagger. The black histogram includes all tagger hits, while the shaded histogram refers only to those tagger hits that have no CPV hit within the veto window. The darker shaded regions indicate the coincidences and accidentals windows. Bin width is 0.5 ns.

of the hits in each of the three counters forming the pixel. The average of these three corrected times for a given pixel is called the "pixel time." Taken relative to the tagger, the pixel time measures the time-of-flight for the recoil particle. An average time-of-flight of 5 ns/m is subtracted from the pixel time to form the "recoil time" which optimizes the time resolution of the BSD relative to the tagger.

Fig. 6 shows the recoil time from the barrel scintillators referenced to the tagger for all level-3 triggers. All tagger hits are treated on the same footing, leading on average to more than one entry in the spectrum per event. In the case where more than one barrel pixel is present in an event, the earliest pixel defines the recoil time. The regularly spaced spikes in the spectrum are significant; they reflect the 2 ns period of the CEBAF beam.

25

Including all tagger hits results in the black histogram in the figure. The shaded histogram results when only the tagger hits that survive the CP veto are used. Accidental vetos cause the overall scale to be suppressed by a factor of 0.7 after the CP veto is applied. The number of counts in the coincidence peak is reduced by much more than this factor, indicating that most of the recoils in the original sample are associated with charged tracks in the forward region. This shows the importance of the CP veto in isolating a clean sample of neutral decays.

The third histogram outlined in gray in the figure illustrates a subtle point regarding the correct treatment of accidentals in the case of CP-vetoed tags. Note that after the CP veto is applied, a depression appears in the level of the accidentals continuum in the vicinity of the coincidence peak. This is because a large fraction of the recoils occur in association with one or more hits in the CPV, even when the event that caused them did not come from a tagged photon. Thus the suppression of tagger hits with CP coincidences not only has the desired effect of removing the charged component from the recoils-tagger coincidence peak but as a by-product it depresses the accidental baseline under the peak. A similar baseline depression must also be present in the accidentals window or an over-subtraction will result when the coincidence-accidentals difference is taken.

The gray histogram in the figure illustrates what results when the correct procedure is applied as follows. The coincidences window is a region in the recoils-tagger timing spectrum of width Δt_c which contains the entire coincidence peak. The accidentals window is an image of the coincidences window shifted by an amount $\Delta t_a \geq \Delta t_c$ so that it contains none of the coincidence peak but samples a common accidentals baseline with what lies within the coincidence window. All tags within a CP veto window of Δt_v relative to any CPV hit in the event are eliminated, and the remaining tags are used relative to the event recoil time to count the coincidence weight for the event. A similar procedure is followed to compute the accidentals weight, except that tags are eliminated which fall in a *shifted* CP veto window, still of width t_v but shifted by Δt_a. This has the effect of removing from the accidentals sample those events which have associated recoil and CPV hits that are not in association with the tagger, in exactly the same way that such events were eliminated from the coincidences sample. The dark shaded region containing the peak in Fig.6 indicates the contribution to the signal from the coincidences window, while the shaded region just to the right of it indicates the accidentals window contribution. Subtraction of the two produces the neutral-tagged yield.

The power of this joint CPV-tagging analysis to isolate a clean sample of neutral γ,p events is demonstrated by the quality of the total energy signal seen in the forward calorimeter in association with a single tagging counter. In the first panel of Fig. 7 is shown the summed energy of all reconstructed
Fig. 7. Summed energy from all reconstructed forward clusters in an event. The sample includes all events with between 2 and 7 clusters, a single recoil and no extra energy in the barrel. The upper panel shows the spectrum corresponding to events in coincidence with tagging counter 19 (solid histogram) at the low-energy end of the tagged momentum bite and counter 1 (dashed histogram) at the high-energy end. The lower panel shows the same two spectra after the CPV-tagging analysis described in the text has been carried out for the same two tagging counters.

showers in the forward calorimeter, for events with a single recoil and no extra charged or neutral energy in the barrel. These spectra are shown in order to demonstrate that a simple event-by-event tagging analysis is ineffectual at these high rates. The dashed histogram is filled for all events that contain at least one coincidence with a selected tagging counter at the high-energy end of the tagger around 5.36 GeV, while the solid histogram is taken in coincidence with a tagging counter at the low end of the tagged range around 4.41 GeV. Little difference can be seen between the two spectra apart from a bulge on the high side of the peak in the case of the higher-energy counter. The

27
Fig. 8. Summed energy from all reconstructed forward clusters in an event before (open histogram) and after (shaded histogram) tagging accidentals have been subtracted. Only tagging channel 10 was included in the analysis, corresponding to a 50 MeV bin in the beam energy spectrum centered at the position of the vertical line. The sample includes all events with exactly 2 reconstructed clusters, a single recoil and no extra energy in the barrel. The curve is a fit to the sum of two Gaussians.

second panel shows the same two spectra after the application of the CPV-tagging analysis described above, applied to the same two tagging counters. The vertical lines indicate the expected median energy of the beam spectrum subtended by the respective tagger channels, as given by the electron beam energy and the field in the spectrometer. A downward shift of about 100 MeV and a tail to lower energies is expected in these spectra because of the energy from the incident photon that is carried away by the recoiling target. This agreement between expectation and measurement in the total energy scale was obtained without fine-tuning, purely on the basis of the LGD calibration that adjusted the observed 2γ mass peaks to align with the physical masses of the π^0 and η.

The counting rates in the two tagging counters shown in Fig. 7 are roughly equal. The difference in the tagged yields for the two counters that is seen in the right plot reflects the decrease in the cross section times acceptance for 1-prong reactions across the momentum bite of the tagger focal plane.

The importance of the accidentals subtraction in the tagging analysis is illustrated in Fig. 8. Only events reconstructed with two clusters in the LGD are included in this sample. The upper open histogram is the total forward energy spectrum for all events in coincidence with a selected tagging counter near the middle of the tagged range and in anticoincidence with the CPV. The lower open histogram is the corresponding accidentals spectrum for the same tagging counter. The shaded histogram is the difference between them, which is the tagged spectrum for that tagging counter. The curve through the tagged spectrum is a fit to the sum of two Gaussians, one representing the central peak and the other associated with the low-energy tail. The r.m.s. width of the central peak of 280 MeV is in good agreement with expectations for the summed energy of two-cluster events as parameterized in Eq. 10 (see section 6.5).

6.3   Radiation Damage

Online monitoring of the LGD during the experiment indicated that the gain 8 blocks immediately adjacent to the beam hole decreased as the run progressed. This observation was based upon the laser monitor system, the raw pulse-height distributions, and the channel gains which were periodically recalibrated during the run, as outlined is Section 4 A similar effect was seen, but to a lesser degree, for the next layer of blocks once removed from the beam hole. During a pause in the experiment, visual inspection of the blocks indicated that the glass was darkening, a well-known effect of radiation damage on lead glass. Fig. 9 illustrates the gain reduction with beam time (roughly proportional to integrated radiation dose) for a typical block adjacent to the beam hole. It is apparent that the gain change is a gradual, cumulative effect rather than a sudden change which might be characteristic of a beam mis-steering event.

The magnitude of the gain loss (order 40%) was such that it could be compensated by adjustments of the PMT high voltages. This was done periodically during the experiment. The last datum in Fig. 9 shows the result of one adjustment. However, this is only a partial solution, since a radiation damaged block produces fewer photoelectrons in the PMT, resulting in a degraded energyt resolution which cannot be compensated by increasing the PMT gain. Thus it was desirable to 'heal' the radiation damage as much as possible.
Fig. 9. The effect of radiation damage on the central part of the detector. The last point shows the gain after an adjustment of the phototube high voltage.

Radiation damage in lead glass is known to be temporary, and to largely heal itself on the time scale of a few months. The healing can be accelerated by the use of ultraviolet (UV) light. This approach was adopted for the most affected blocks. During an extended down-time in the run, the PMT and base for selected modules were removed and a UV light guide attached to a quartz-envelope Mercury vapor lamp was inserted. The output of the lamp was 5 W/cm^2 in the range 300 to 480 nm, with a peak intensity at 365 nm. The affected blocks were each illuminated for periods of 6-8 hours. These blocks showed a gain increase of 30% following this treatment, nearly recovering their initial performance.

It should be noted that the change in the response of the modules due to radiation damage and the gain recovery following UV treatment was even more dramatic in the data from the laser monitoring system (typically a factor of two change). The difference between the shift in the pulser response and that seen in the gain constants from the calibration can be qualitatively understood

30

Table 4
Event yields at successive stages in the RADPHI analysis, broken down according to shower multiplicity in the forward calorimeter.

sample	2γ	3γ	4γ	5γ	6γ	7γ
on tape	2.29×10^8	2.47×10^8	2.12×10^8	1.34×10^8	7.16×10^7	3.50×10^7
tagged [1]	9.05×10^7	1.06×10^8	9.35×10^7	5.89×10^7	3.06×10^7	1.42×10^7
cp veto [2]	3.27×10^7	2.34×10^7	1.72×10^7	8.09×10^6	3.50×10^6	1.33×10^6
1-prong [3]	2.50×10^7	1.81×10^7	1.33×10^7	6.27×10^6	2.71×10^6	1.02×10^6
fiducial cut [4]	2.28×10^7	1.36×10^7	8.93×10^6	3.55×10^6	1.36×10^6	4.45×10^5
barrel γ detector [5]	3.83×10^6	1.89×10^6	1.29×10^6	4.59×10^5	1.65×10^5	4.33×10^4

[1]after subtraction of accidental tags

[3]single isolated charged hit in barrel scintillators
[4]no showers in LGD located on inner and outer boundaries
[5]no energy in BGD apart from that associated to recoil proton

by noting that the laser illuminates the front of the block and thus measures the transmission of the entire block, while the showers seen in the calibration data create Cerenkov light throughout the volume of the block, and are therefore less sensitive to attenuation effects in the upstream region of the block. The radiation damage is expected to be concentrated within one or two radiation lengths of the front surface of the detector, and this was confirmed by visual inspection, in qualitative agreement with the difference between the laser monitor data and the calibration data.

6.4   Yields

The integrated live-time of the experiment under standard operating intensity and trigger was 1.56×10^6 seconds corresponding to an integrated luminosity of 27.1 pb^{-1} in γ^9Be interactions within the tagged region of the beam photon spectrum. If nuclear corrections may be neglected, this corresponds to a little over 100 pb^{-1} in γp interactions. The trigger acceptance for γp→pX reactions where X decays to all-neutral final states is on the order of 50%, where losses come mainly from absorption of the recoil proton in the target and escape of final-state gammas through the forward hole in the calorimeter.

The total numbers of events collected and reconstructed at successive stages in the analysis are shown in Table 4 broken down according to the shower multiplicity in the forward calorimeter. The sample shown in a given row consists

of all events shown on the previous row that satisfy the one additional require-
ment listed in column 1. None of the cuts shown actually modify the way a
given event is reconstructed, so there is no cross-over between the columns
and each column represents an independent and distinct set of initial triggers.
Which multiplicity is assigned to a given event depends upon the tuning of
the cluster-finding algorithm. The results shown in the table were obtained
with settings which give an acceptable trade-off between under-counting and
over-counting of clusters.

6.5   Energy and position resolution

Lacking a source of electron or photon showers of a well-defined energy, the
RADPHI experiment had to rely on the observed width of known mesons to
deduce the energy resolution of the lead-glass calorimeter. The observed width
of narrow mesons such as the π^0 and η that undergo 2γ decay is determined by
the single-shower energy and position resolutions of the LGD. In cases where
the spatial contribution can be neglected, the single shower energy resolution
was extracted by selecting pairs with one of the two showers in a narrow energy
window and examining the energy spectrum of the other, for a given cluster-
separation angle. This energy spectrum shows peaks that correspond to the
masses of the π^0 and η and whose line-shapes are convolutions of the energy
response functions for the two showers plus contributions from uncertainties on
the shower centroid positions. The contribution from spatial resolution to the
width of the peaks was minimized by focusing first on the η, which is associated
with pairs of showers that are well separated on the face of the calorimeter. By
analyzing the dependence of the peak width on the energies of the individual
showers, the convolution was inverted to obtain the r.m.s. resolution for single
showers as a function of shower energy without introducing a model for the
energy dependence. Once the energy resolution had been determined in this
way, the spatial resolution was then examined by looking at the excess width
of the π^0 peak over what was expected based upon energy resolution alone. In
the end, a unified analysis including both energy and spatial resolution effects
was able to reproduce both the π^0 and η profiles.

Assuming that the spatial resolution is not important for $\eta(2\gamma)$ decays, the
r.m.s. shower energy resolution can be extracted without assuming any func-
tional form for its dependence on shower energy. This model-independent so-
lution was then compared with the standard parametrization [17] of the lead
glass energy resolution

$$\frac{\sigma_E}{E} = \frac{B}{\sqrt{E}} + A. \tag{10}$$

The first term on the right contains the effects of photoelectron statistics, while the second term wraps up all of the systematic block-to-block differences and calibration errors which prevent the width of the response function from collapsing to a delta function in the high-energy limit. In order to describe the π^0 peak with the same parameters it is necessary to introduce a model for the shower spatial resolution, which itself depends upon shower energy. The energy dependence is proportional to $1/\sqrt{E}$ with a proportionality constant that depends on the size of the LGD block [18]. Eq. 11 is adopted for showers at normal incidence, with the constant C expected to be around 7 mm·GeV$^{-\frac{1}{2}}$.

$$\sigma_x = \frac{C}{\sqrt{E}}. \tag{11}$$

In the RADPHI geometry many of the showers are far from normal incidence and so shower depth fluctuations of roughly one radiation length also contribute to the centroid position resolution along one of the spatial axes. This was taken into account in the analysis by projecting one radiation length from along the shower axis onto the transverse plane and adding it in quadrature to the base term in Eq. 11. The final values for all parameters were determined by simultaneous analysis of the η and π^0 data where all of the above effects are included for both.

The invariant mass-squared of two photons is given by

$$m^2 = 2E_1 E_2 (1 - \cos\theta_{12}), \tag{12}$$

where E_1 and E_2 are the corresponding photon energies and θ_{12} is their angular separation. The expression for the variance of m^2 in terms of the variances V_E on the shower energies and V_x, V_y on the shower positions is given by

$$V_{m^2} = \sum_{i=1}^{2} \left[\left(\frac{\partial m^2}{\partial E_i}\right)^2 V_{E,i} + \left(\frac{\partial m^2}{\partial x_i}\right)^2 V_{x,i} + \left(\frac{\partial m^2}{\partial y_i}\right)^2 V_{y,i} + 2\left(\frac{\partial m^2}{\partial x_i}\right)\left(\frac{\partial m^2}{\partial y_i}\right) V_{xy,i} \right], \tag{13}$$

where index i counts photons, and $V_{xy,i}$ is the covariance between the x and y coordinates of the shower centroid for shower i. Eq. (13) can be rewritten in the form

$$\frac{V_{m^2}}{m^4} = \frac{V_E(E_1)}{E_1^2} + \frac{V_E(E_2)}{E_2^2} + \frac{V_s(m^2)}{m^4}, \tag{14}$$

where spatial derivatives and variances are grouped into the term $V_s(m^2)$. A lengthy but straight-forward calculation gives V_s in terms of the underlying

position uncertainties of the two showers. For example, the contribution from the x coordinate of shower 1 is given in by

$$\frac{\partial m^2}{\partial x_1} = -\frac{2p_{z,1}}{z_0 \, E_1^2} \left[p_{x,2} \left(p_{y,1}^2 + p_{z,1}^2 \right) - p_{x,1} \left(p_{y,1} \, p_{y,2} + p_{z,1} \, p_{z,2} \right) \right], \tag{15}$$

where component $k = 1, 2, 3$ of reconstructed shower shower $j = 1, 2$ is written $p_{k,j}$. The other spatial derivatives have a similar form and they can be obtained by the proper variable substitution in Eq. 15. The position z_0 of the shower maximum is not directly measured, but from Monte Carlo it is estimated to be 120 cm from the target (about 20 cm into the glass) and weakly dependent on energy. The results of the resolution analysis are not sensitive to changes in z_0 on the order of one radiation length. The fact that departure from normal incidence cannot be ignored requires a treatment of centroid errors that couples the uncertainties in the x and y coordinates. The results are summarized in Eqs. 16-18.

$$V_x = \frac{C^2}{E} + (X_0 \sin \theta \cos \phi)^2 \tag{16}$$

$$V_y = \frac{C^2}{E} + (X_0 \sin \theta \sin \phi)^2 \tag{17}$$

$$V_{xy} = X_0^2 \sin^2 \theta \cos \phi \sin \phi \tag{18}$$

The geometry and material properties of the LGD lead to nominal values $C = 7.1$ mm·GeV$^{\frac{1}{2}}$ and radiation length $X_0 = 31.6$ mm[19].

The η sample used in the resolution study contained 8M events. Pairs were selected with shower separation $D_{\gamma\gamma} \geq 20$ cm to enhance the η peak, as shown on the right side of Fig. 10. The π^0 sample consisted of $15M$ events selected by limiting the invariant mass $m < 0.5$ GeV/c^2. The corresponding invariant mass distribution is shown on the left side of Fig. 10 contains $8M$ events. The π^0 and η peaks are fitted with a Gaussian over a polynomial background. The width of the η peak receives only a few percent contribution from the V_s term in Eq. 14. Neglecting this contribution permitted a model-independent extraction of the energy dependence of the single-shower energy resolution in the LGD, as described above. The results are shown by the data points in Fig. 11. They are in good agreement with a fit based upon the form of Eq. 10 indicated by the solid curve in the figure. Including the spatial contribution in Eq. 14 in the fit and allowing C to vary as a free parameter leads to the dashed curve in Fig. 11 which lies very close to the solid curve, showing that spatial resolution plays an insignificant role in determining the observed width of the η in this sample.

If the results of the analysis of the η width are applied to the π^0 sample, the

Fig. 10. Invariant mass distribution of $\pi^0(2\gamma)$ (left) and $\eta(2\gamma)$ (right). The parameters shown are the height (P1), mean (P2) and sigma (P3) of the Gaussian peak fitted to the data over a polynomial background described by parameters P4-P6.

predicted widths come out smaller than the measured widths by about 40% when the spatial contribution is neglected. This indicates that the spatial and energy resolution contributions are comparable in the case of the π^0. A global analysis was applied to both the η and the π^0 samples in which both the energy and spatial contributions to the error were included in a uniform way. A total of 50 measured widths taken from different regions in photon energies and separation angles were used as inputs, and the constants A, B and C were treated from Eqns. ?? and ?? as free parameters in the fit. The results of the fit for the energy resolution are shown by the dotted curve in Fig. 11. The

LGD shower energy resolution
Fig. 11. Energy resolution of showers in the LGD obtained from analysis of the 2γ sample. Points represent the free solution to the η squared-mass resolution measurements when the contribution from the spatial resolution has been neglected. The solid line represents the fit to the η data with the standard energy resolution model. The dashed line represents the fit to the η data when the spatial contribution is taken into account by Eq. (14). The dotted line corresponds to the simultaneous fit to the η and π^0 data with the same function.

best-fit values from the fit were $A = 0.035 \pm 0.008$, $B = 0.073 \pm 0.006$ GeV$^{\frac{1}{2}}$ and $C = 6.4 \pm 0.1$ mm·GeV$^{\frac{1}{2}}$. The χ^2 returned by the fit is 1.5 per degree of freedom.

7 Conclusions

The RADPHI detector was able to detect exclusive final states consisting of up to seven photons. The calibration, trigger and reconstruction techniques developed worked well in the challenging high-rate environment of a CW photon

36

beam. Acceptable resolution was achieved down to energies lower than 1 GeV. The detector was able to survive the high rate environment with minor and correctable radiation damage.
